Ensemble Methods

1 Bagging (Bootstrap Aggregating)

Bagging tackles high model variance by making dozens, even hundreds of “bootstrap” copies of the training set, each built with sampling-with-replacement. A separate base learner trains on every copy, and their predictions are blended (majority vote or mean). Because each learner sees a slightly different view of the data, their errors scatter; the ensemble average smooths them out, yielding sturdier forecasts and less over-fitting [1, 2]

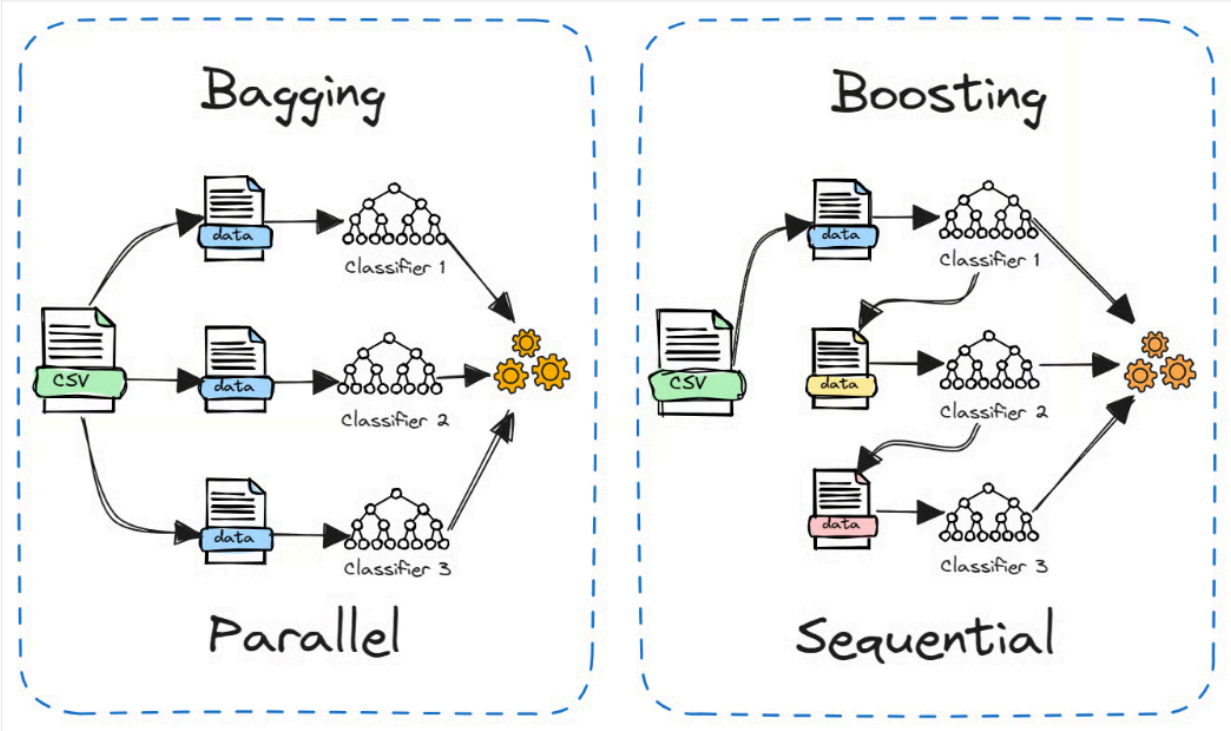

Figure 1. DataCamp’s schematic shows original data feeding three bootstrap samples, three parallel trees, and a final voter that outputs the ensemble prediction [13]

Boosting

Boosting flips bagging on its head: weak learners line up in sequence, each one focusing harder on the cases its predecessors missed. Instance weights rise on every mis-classification, steering later models toward tough examples. The ensemble’s final vote is a weighted sum, so later, better-targeted learners speak louder. The chain effect slashes bias and can turn “just-better-than-random” stumps into a champion predictor [3, 4].

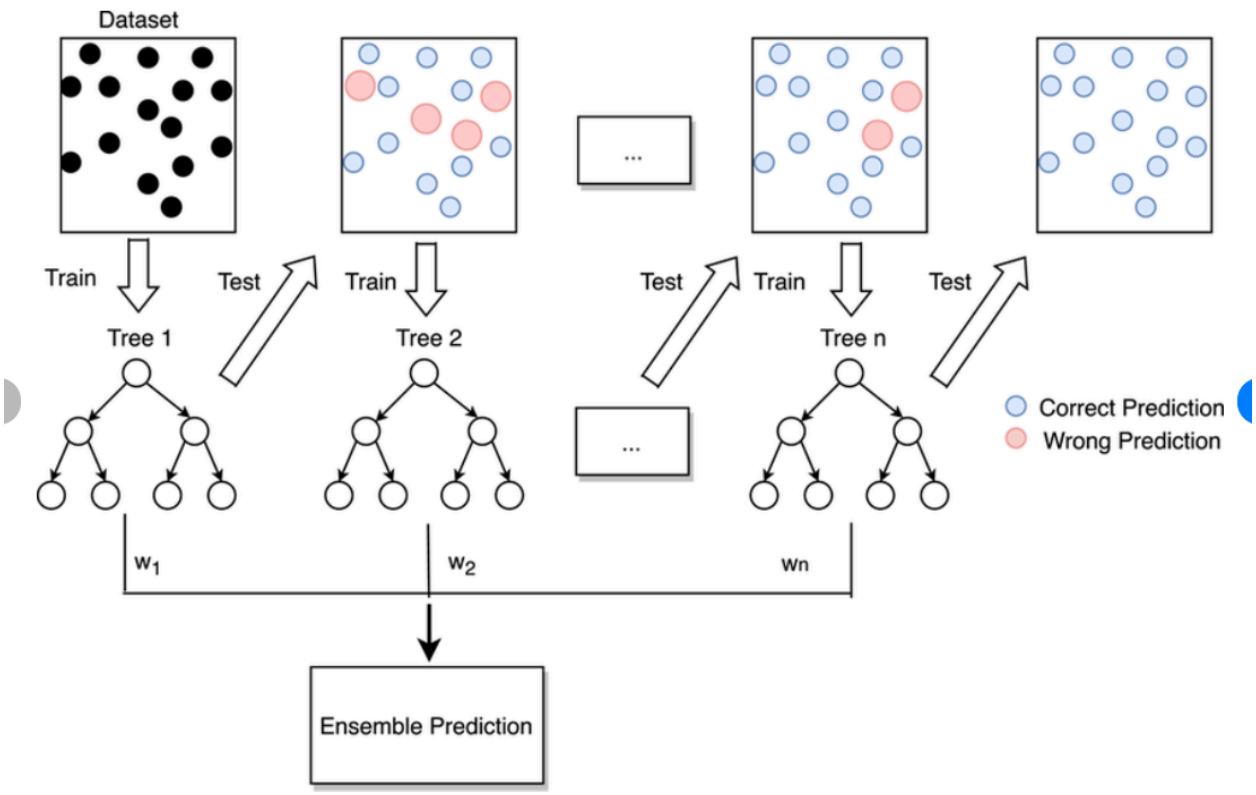

Figure 2. Flow diagram of gradient boosting machine learning method. The ensemble classifiers consist of a set of weak classifiers. The weights of the incorrectly predicted points are increased in the next classifier. The final decision is based on the weighted average of the individual predictions. [14]

3 Random Forests

A random forest is bagging plus an extra twist: when each tree splits, it considers only a random subset of features. That forced diversity means trees disagree even more, so the forest's majority vote is rarely swayed by any single quirky variable. In practice, forests work "out of the box" for both regression and classification, handle missing data gracefully, and provide handy feature-importance scores [5, 6].

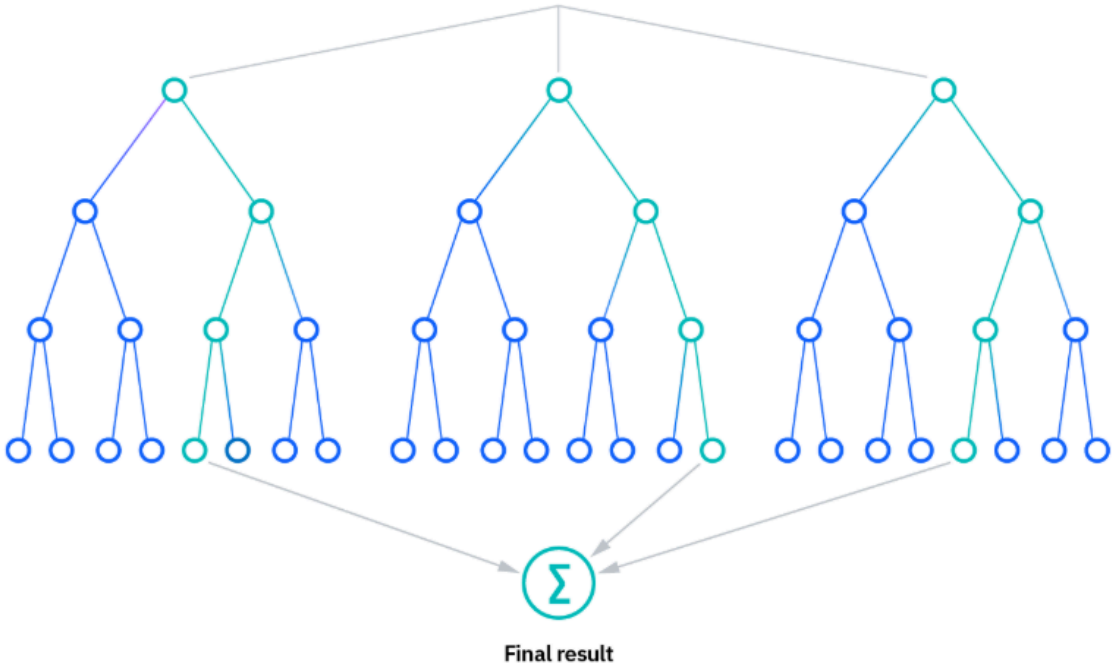

Figure 3. IBM's primer depicts many decorrelated trees voting on the most probable class—highlighting how both row and column-level randomness feed model strength.

4 Stacking (Stacked Generalization)

Stacking blends *different* model families instead of carbon-copy learners. Each base model predicts on held-out folds; those predictions form a new "meta" data set. A higher-level learner (the *meta-model*) then learns which base model to trust where. Because correlations among errors shrink when algorithms differ, the meta-model uncovers complementary strengths and beats any single one[7, 8].

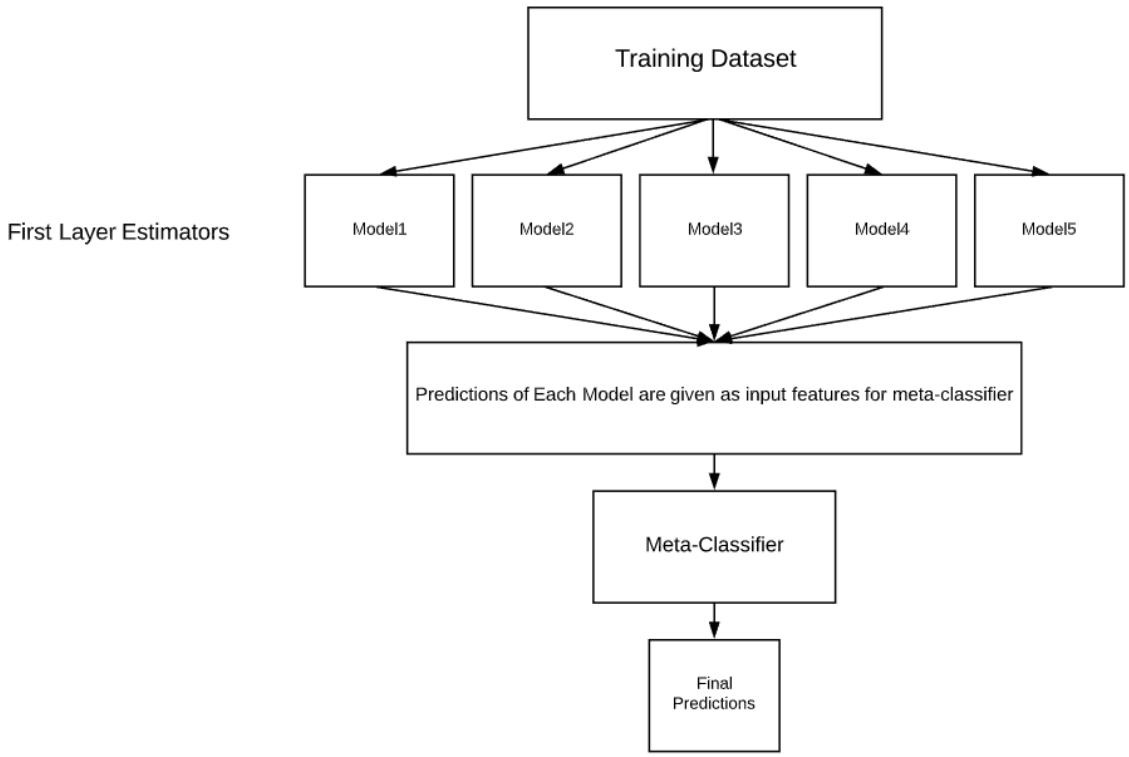

Figure 4.A clean, one-page schematic from GeeksforGeeks shows the full stacking workflow [7].

Unsupervised Learning

5 k-Means Clustering

k-Means seeks natural groupings without labels. It picks *k* random centroids, assigns every point to its nearest centroid, then drags each centroid to the mean of its new cluster. Repeat those two steps until assignments stabilize. The result: compact, spherical clusters that minimize within-group squared distance. Elbow, Silhouette, or Gap statistics help choose *k*. While simple and fast, k-Means stumbles on irregular shapes or vastly different cluster sizes [9, 10].

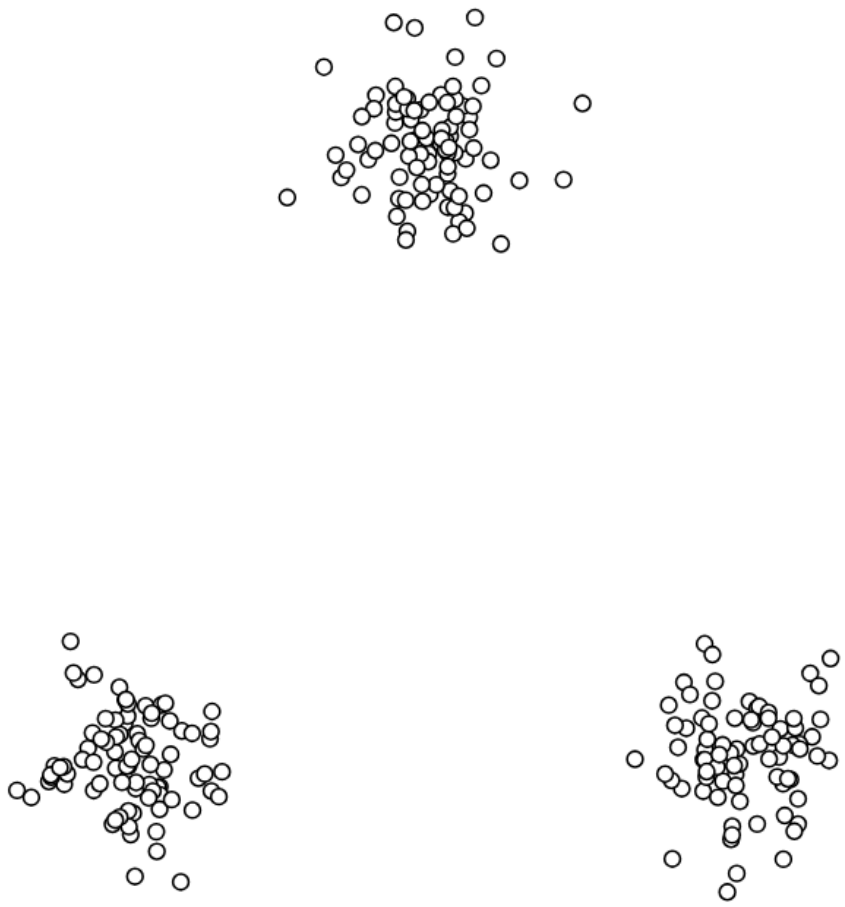

Figure 5. Naftali Harris's animated Voronoi diagram clarifies the assign-and-update dance of centroids, which is ideal for a visual walkthrough [15].

6 Principal Component Analysis (PCA)

PCA remodels high-dimensional data by spinning the axes to new, orthogonal directions that capture maximum variance. The first principal component grabs the greatest spread; each subsequent component, ranked by descending variance, is perpendicular to all earlier ones. By keeping only the top few PCs, we cut noise and redundant dimensions while preserving most information, for visualization and speedy downstream learning. Because no labels guide the rotation, PCA is quintessentially unsupervised [11, 12].

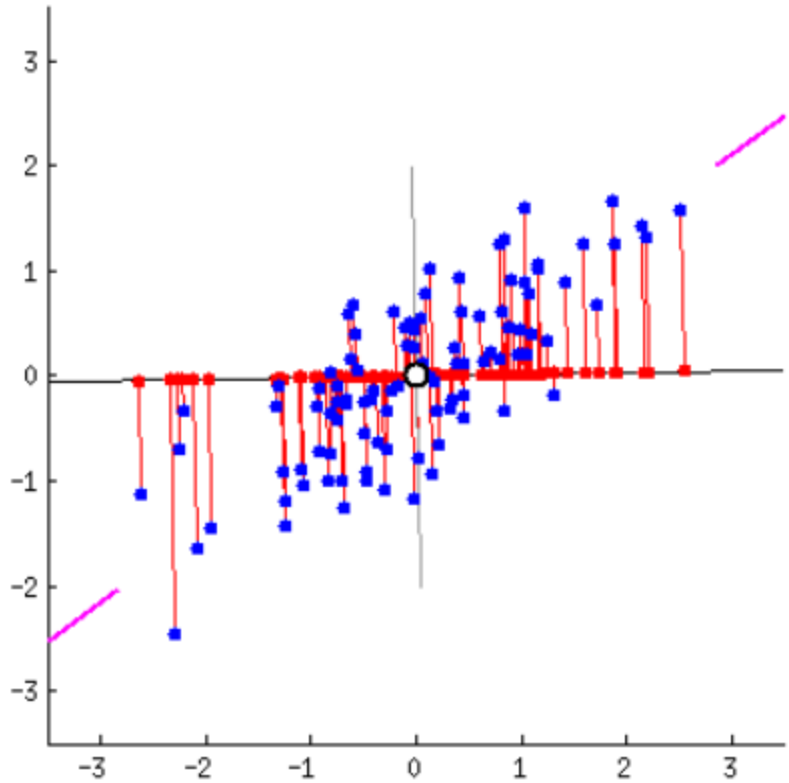

Figure 6. Built-In's scatter plot shows data projected onto PC1 vs. PC2 with arrows marking the original axes highlight how the cloud elongates along variance-heavy directions [16].
